

Participation Constraints in the Stock Market: Evidence from Unexpected Inheritance Due to Sudden Death

Steffen Andersen

Kasper Meisner Nielsen

Hong Kong University of Science and Technology

We use a natural experiment to investigate the impact of participation constraints on individuals' decisions to invest in the stock market. Unexpected inheritance due to sudden deaths results in exogenous variation in financial wealth, and allows us to examine whether fixed entry and ongoing participation costs cause non-participation. We have three key findings. First, windfall wealth has a positive effect on participation. Second, the majority of households do not react to sizeable windfalls by entering the stock market, but hold on to substantial safe assets—even over longer horizons. Third, the majority of households inheriting stock holdings actively sell the entire portfolio. Overall, these findings suggest that participation by many individuals is unlikely to be constrained by financial participation costs. (*JEL* D14, G11)

Few households participate—directly or indirectly through mutual funds—in the stock market. In the absence of participation constraints, this non-participation is puzzling, as standard models of lifetime consumption and portfolio choice predict that all households, no matter how risk averse, should invest in stocks (Samuelson 1969; Merton 1969, 1971; Arrow 1971). In this study, we use a natural experiment to test whether non-participation is caused by participation costs. Exogenous variations in wealth result from unanticipated inheritance due to sudden death and allow us to identify whether individuals face participation constraints in the stock market. Our results reveal that

for the majority of households, non-participation is unlikely to be explained by financial constraints.

At present, the leading explanation for non-participation in the stock market is fixed entry or ongoing participation costs of some kind. These costs capture anything from transaction costs to time spent on information gathering and preparation of tax returns.¹ Such pecuniary costs can explain non-participation simply because many households have insufficient wealth to make participation worthwhile. For instance, Vissing-Jørgensen (2002) demonstrates that a moderate per-period cost of USD 50 (USD 260) in year-2000 prices is sufficient to explain why half (three-quarters) of non-stockholders in the United States do not participate.² Empirical studies invariably find a strong positive correlation between wealth and stock market participation, which in turn is interpreted as evidence of participation costs.

Alternatively, fixed costs may be an economist's pecuniary representation of behavioral and psychological factors that make equity ownership uncomfortable for some households. Although economic, behavioral, and psychological explanations are likely to coincide, prior literature has not been able to identify the relative importance of these explanations for non-participation. Consequently, the inability to pinpoint source(s) of non-participation makes it difficult to promote wider stock ownership. In essence, the fixed-cost explanation requires more involved economic policies aimed at lowering the costs and facilitating participation, whereas financial education might limit the effect of behavioral and psychological barriers.

In this article, we use a natural experiment to formally test whether fixed entry and ongoing participation costs cause non-participation. We use windfall wealth from unexpected inheritance due to sudden death as a plausible source of exogenous variation to identify how these frictions explain non-participation. If fixed entry and participation costs restrict participation, we would expect individuals to respond to windfall wealth by entering the stock market. If, however, behavioral, cognitive, and psychological explanations are in play, even sizeable windfalls will have little impact on participation.

Our empirical identification strategy relies on a conservative medical definition of sudden death and unique cause-of-death data from official death certificates to identify 10,344 cases out of 346,788 deaths in Denmark over a period of six years. Each case is classified as medically unexpected and sudden *as well* as having resulted in the termination of the household, potentially increasing the beneficiary's wealth. While constituting tragic events, these sudden

¹ Prior literature provides myriad examples of fixed (pecuniary) costs, but no stringent definition. Examples include trading costs; one-time learning costs; and time and money spent on everything from keeping up with market developments, and choosing and monitoring portfolio investments, to filling out tax forms. Fixed entry costs are one-time outlays related to entering the stock market, whereas participation costs are expenses related to staying in the market.

² Vissing-Jørgensen (2002) estimates the fixed per-period cost by calculating the benefit of stock market participation given observed individual financial wealth and an after-tax equity premium of 5.6%.

deaths help us identify 17,191 beneficiaries who received a windfall. To the best of our knowledge, this is the first study that seeks to examine barriers to stock market participation using exogenous variation from one of nature's own experiments.

The advantage of our identification strategy is fourfold. First, as windfall wealth from unexpected inheritance is unrelated to current economic and stock market conditions, it is reasonable to attribute a positive effect of inherited wealth on stock market participation to the existence of fixed participation costs. Second, by exploiting the variation in the characteristics of beneficiaries, we can enhance our understanding of fixed entry and ongoing participation costs. In particular, we are interested in examining whether the effect of windfall wealth is larger for individuals whom the prior literature has identified as having low entry and participation costs. Third, detailed information on the composition of inherited wealth allows us to identify the effect of procrastination by decomposing inherited wealth into inherited stocks and inherited cash. Inheriting an estate that holds stocks alters the active decision from one of choosing to enter the stock market to one of choosing to exit it. If procrastination drives non-participation, we would expect to find an additional effect on participation from inheriting a dollar's worth of stock when compared to the effect of inheriting the same value in cash. Fourth, our strategy allows us to control for unobserved individual characteristics (e.g., ability and social heritage) that are likely to correlate with income and wealth.

Although our empirical identification relies on deaths that medical records classify as sudden and unexpected, we cannot exclude the possibility that some deaths might have been anticipated by the immediate family. To address this concern, we provide a robustness check that focuses exclusively on accidents, in which death is less predictable.

Our results reveal that some individuals face entry and ongoing participation costs in the stock market. Receiving a windfall of one million Danish kroner (DKK), equivalent to EUR 134,000, raises an individual's probability of entering the stock market within the following three years by approximately 21 percentage points, which still leaves the majority of individuals as non-participants.

We further analyze the time window to determine whether these results are driven by investment inertia caused by individuals slowly reallocating their portfolios. Even though some individuals delay entry, we find that the vast majority of entrants invest in the stock market within three years. While our results document the existence of entry and participation costs in the stock market, they also show that a surprisingly large fraction of individuals who receive considerable windfalls continue to not participate—even over longer horizons. These surprising observations hold even for highly educated and financially literate individuals who possess knowledge about the stock market. Still, among these individuals, a large fraction stays out of the stock market after receiving a sizeable windfall.

We also examine the contention made in much of the literature that procrastination is an important factor in understanding individuals' often inadequate savings for retirement. Procrastination might cause low stock market participation if individuals neglect to invest out of carelessness or laziness. We test the impact of procrastination by analyzing the effect of inheriting stocks rather than cash. As the fixed entry costs of participation are reasonably similar in the two cases, any difference in participation rates can largely be attributed to the effect of procrastination.³ Among households that inherit stock holdings, the majority of individuals actively exit the stock market by selling the entire position. This finding limits the viability of participation costs as the leading explanation for the participation puzzle.

Finally, we document that non-participants keep a substantial fraction of their inheritance in financial assets. In particular, financial wealth in bonds and cash increases significantly following an inheritance. Households that receive a windfall of at least DKK 1,000,000 keep, on average, DKK 512,000 (EUR 68,700) in financial wealth. Thus, non-participants choose to forego participation benefits that are large enough to compensate for fixed entry costs. Overall, our results demonstrate that although fixed entry and participation costs exist, they are unlikely to explain why the majority of households are non-participants.

An understanding of the barriers to participation offers better insight into why individuals shy away from the stock market. This insight is important because limited participation has serious implications for economic welfare, financial markets, and an individual's expected lifetime income and consumption. Stock market participants enjoy higher lifetime consumption (Mankiw and Zeldes 1991), and foregone consumption often exceeds 2% of annual consumption (Cocco, Gomes, and Maenhout 2005). The lower expected lifetime consumption persists even when taking into account the fact that many non-participants would most likely be inefficient investors who incur lower returns (Calvet, Campbell, and Sodini 2007). As pointed out by Campbell (2006), a better understanding of the participation constraints also helps us evaluate whether individuals make investment mistakes, and whether financial educators can reduce the incidence and welfare costs of such mistakes. On this important issue, our results show that although fixed participation costs keep some individuals out of the stock market, the vast majority of individuals do not respond to significant windfall wealth. For those individuals, other barriers, such as behavioral, cognitive, and psychological constraints, are likely to dominate.

³ The difference in the fixed cost of inheriting cash to that of inheriting stocks relates to the difference between initial transaction costs and transfer fees associated with moving the stocks from the estate to the beneficiary's brokerage account. As any difference between these costs accounts for a trivial fraction of the total fixed costs, it seems reasonable to assume that differences in fixed entry costs are independent of whether an individual inherits cash or stocks.

The rest of the article proceeds as follows. Section 1 describes the motivation and background of the article. Section 2 outlines our data and presents summary statistics and our empirical strategy. Section 3 presents the results of the article. Section 4 provides robustness checks using alternative specifications, and Section 5 presents our conclusions.

1. Motivation and Background

In the standard models of lifetime consumption and portfolio choice, an individual's lifetime utility is maximized by choosing consumption, and by holding a mix of safe and risky assets (Samuelson 1969; Merton 1969, 1971; Arrow 1971). A central result in these models is that all individuals should invest in the same portfolio of risky assets, with the individual's risk aversion determining the actual allocation between risky and safe assets. The standard models, therefore, predict that it is optimal for all individuals to hold at least a fraction of stocks in their portfolio and, thus, to participate in the stock market.

In contrast, it has long been observed empirically that stock market participation is far from universal (Blume and Friend 1975, 1978; King and Leape 1984; Mankiw and Zeldes 1991). Although participation varies greatly across countries and has increased recently (Guiso, Haliassos, and Jappelli 2003; Giannetti and Koskinen 2010), the overall impression is that participation is still low (Campbell 2006). As the observed limited participation contrasts with the theoretical predictions of the standard models, it follows that this discrepancy points to a failure in one of the underlying assumptions.

Non-participation has generally been explained by moderate fixed costs related to entry and ongoing participation (Haliassos and Bertaut 1995; Vissing-Jørgensen 2002, 2003). Such fixed costs capture the time and money spent in order to invest in the stock market. These time and money costs may include any costs related to learning about stocks, acquiring information, trading, monitoring the portfolio, or preparing tax forms, which tend to become more complicated with equity ownership. Examining the magnitude of these costs, Vissing-Jørgensen (2002) demonstrates that a per-period cost of USD 50 (USD 260) in 2000 prices is enough to explain why half (three-quarters) of non-stockholders do not participate: These individuals simply have insufficient financial wealth to make participation worthwhile. While this result is not based on a formal test for the presence of such fixed costs, it does provide an economic estimate of whether participation costs are a likely explanation of limited participation. Fixed costs, however, cannot explain non-participation among wealthy households.

Several preexisting studies have demonstrated cross-sectional variation in stock market participation in keeping with the fixed-cost argument. In particular, participation generally increases with wealth, age, and education (see Mankiw and Zeldes 1991; Haliassos and Bertaut 1995; Bertaut 1998; Poterba and Samwick 2003; Guiso et al. 2003; Vissing-Jørgensen 2003). If participation

is costly, it should increase with wealth because larger portfolios are more likely to be able to incur such costs. Moreover, the fixed-cost argument also predicts that the population of participants should be older than the population of non-participants because individuals will continue to participate once a fixed entry cost has been paid.⁴ Because of their knowledge and lower information costs, highly educated individuals are generally perceived as having lower fixed costs and, hence, a higher participation rate.⁵ In addition, prior literature has demonstrated a strong dependence in the decision to hold stocks over time, which is consistent with the existence of fixed entry costs (Vissing-Jørgensen 2003).

Fixed costs may be the economist's representation of individual characteristics or psychological factors that make equity ownership uncomfortable for some households, as pointed out by Campbell (2006). Through theoretical and empirical analyses, several psychological explanations for non-participation have emerged. Many of these contributions focus on the individual's aversion to the uncertain outcomes of gambling, such as ambiguity aversion (Knox 2003), loss aversion (Ang, Bakaert, and Lui 2005; Dimmock 2005), and loss aversion combined with narrow framing (Barberis, Huang, and Thaler 2006). Other studies have focused on behavioral or psychological factors, such as an individual's (over-) optimism (Puri and Robinson 2007), subjective assessment of stock market performance (Biais, Bossaerts, and Spatt 2004; Dominitz and Manski 2005), lack of trust in financial markets (Guiso, Sapienza, and Zingales 2008), and (low) experienced stock returns (Malmendier and Nagel 2010). More recently, Christelis, Jappelli, and Padula (2009) and Grinblatt, Keloharju, and Linnainmaa (2009) have documented a positive relation between participation and intelligence. According to these studies, non-participation is an investment mistake that households with high fixed costs are more likely to make. In a related study, Hong, Kubik, and Stein (2004) find that social households are more likely to invest due to peer effects.

Even though considerable empirical evidence suggests that fixed costs and psychological barriers explain non-participation, prior empirical literature has relied mainly on cross-sectional variation, which makes it difficult to control for individual heterogeneity, and to separate the fixed costs argument from the behavioral and psychological explanations. Although several studies have used panel data in an attempt to overcome these problems (e.g., Guiso, Haliassos,

⁴ If one studies the entry decision, the fixed entry cost argument implies that younger individuals, *ceteris paribus*, should be more likely to enter the stock market because they can benefit from participation over a longer horizon.

⁵ Consistent with findings of lower fixed costs for educated individuals, Christiansen, Joensen, and Rangvid (2008) show that economists are more likely to participate in the stock market. In related results, Calvet, Campbell, and Sodini (2009) show that financially sophisticated investors are more likely to enter and less likely to exit the stock market.

and Jappelli 2001; Vissing-Jørgensen 2003; Calvet, Campbell, and Sodini 2007; 2009), changes in income and wealth are unlikely to be random. As a result, it is difficult to establish whether the positive income and wealth effects on participation are caused by fixed costs, omitted factors (such as unobservable individual characteristics), or macroeconomic trends that affect income, wealth, and investment opportunities. Moreover, separating age effects from time and cohort effects in cross-sectional data is impossible.

Empirical identification in cross-sectional analysis is also complicated by the fact that the fixed costs and the psychological barrier arguments predict relationships that are observationally equivalent. For instance, the objective-cost argument predicts that better-educated individuals should participate more because they face lower costs, whereas according to the behavioral and psychological explanations, education makes it more likely that the household has learned that non-participation is an investment mistake. A similar argument can be made about the uncovered relation between cognitive abilities (intelligence) and participation. Thus, although prior literature has documented that education, type of education (economics), and intelligence have a positive effect on participation, we do not know whether this is due to fixed costs, or behavioral or psychological barriers.

We use exogenous variation in wealth to overcome these concerns. Our candidate source of exogenous variation in wealth arises from unexpected inheritance due to the sudden death of an individual's parents. In terms of methodology, Brunnermeier and Nagel (2008) are the closest to our study. They use panel data from Panel Study of Income Dynamics (PSID) surveys of US households to identify the effect of changes in liquid wealth on an individual's asset allocation and show that an individual's risk aversion is constant over time. Brunnermeier and Nagel (2008) instrument liquid wealth with quintile dummies for reported income growth and inheritance receipts to ascertain that their results are not driven by measurement errors. The instrumental variable estimation is focused on the asset allocation of participating households.

We extend this line of inquiry by focusing entirely on whether stock market participation is induced by windfall wealth that results from sudden death. The focus on unanticipated inheritance is essential to our study, as expected inheritance cannot convincingly identify the causal relationship between fixed costs and stock market participation. In precise terms, expected inheritance is likely to have a negative bias on the effect of inherited wealth on stock market participation because terminal patients have an economic incentive to distribute wealth to beneficiaries before their deaths in order to minimize estate taxation. Thus, expected inheritance is likely to negatively bias the estimates of the relative importance of fixed entry and participation costs because we cannot observe these transfers. In an effort to overcome such problems, we focus exclusively on windfall wealth from unexpected inheritance due to sudden death.

2. Nature's Own Experiment: Windfall Wealth from Unexpected Inheritance Due to Sudden Death

Identifying exogenous variation in an individual's wealth poses a major empirical challenge. We posit that there exist at least two good candidates from hitherto unexplored sources: lottery prizes and unexpected inheritance. Although lotteries are random draws, they require participation, which introduces a potential selection bias. Unexpected inheritance resulting from sudden death, on the other hand, is a truly random experiment. Because all individuals have legal parents, no selection of individuals takes place except by means of the death event. Thus, for this identification strategy to work, the death has to be unexpected and sudden.

A sudden death is medically defined as an unexpected death that occurs instantaneously or within a few hours of an abrupt change in the person's previous clinical state. For instance, the American Academy of Pediatrics (2009) defines sudden cardiac death as a non-traumatic, nonviolent, unexpected event resulting from sudden cardiac arrest within six hours of a previously witnessed state of normal health. As sudden death is, by nature, a random draw, inheritance that results from sudden death is a natural experiment that induces exogenous variation in an individual's wealth. We consequently assemble a unique dataset from Denmark that allows us to identify windfall wealth from unexpected inheritance and relate it to stock market participation.

The possibility that inheritance is anticipated for some individuals or that individuals might borrow against (even unexpected) inheritance could appear to weaken our identification strategy. We approach these prospects in the following way. To ascertain that the timing of the inheritance is unanticipated, we provide a very narrow medical definition of sudden death. We also note that if the size of the bequests is somewhat anticipated, previous studies underestimate household wealth and thus overstate the ability of participation costs to explain non-participation. To bolster our main argument that sudden bequests provide an exogenous wealth shock, we interact inherited wealth with age and restrict the sample to individuals for whom the shock is more unanticipated—either because of an accident or because both parents die suddenly within the same year. We also control for differences in anticipated bequests related to expected parental consumption (prior to death) by including parental age among the match characteristics. Collectively, these results provide evidence consistent with our identification strategy.

In addition to offering unique data access, the Danish legal environment eases the identification of estates and their heirs. The Danish Inheritance Act of 1964 divides relatives into three groups: Group 1 consists of the deceased's spouse, children, and grandchildren; Group 2 includes the deceased's parents and siblings (and, secondarily, their children); and Group 3 comprises grandparents and their children. By default, relatives in Group 1 inherit the estate. If no Group 1 (2) relatives exist, the relatives in Group 2 (3) are eligible to

inherit the deceased's wealth. The division of the estate within Group 1 is pre-determined, with one-third transferred to the spouse and two-thirds distributed equally among the children unless the spouse chooses to delay the children's inheritance until her own death. Grandchildren inherit their parent's proportional share if their parent is deceased. Similar default sharing rules exist for Group 2 and 3 relatives.

In the analysis, we focus on cases in which Group 1 relatives exist and the suddenly deceased was a widow (or, in rare cases, a deceased couple). We refer to these cases as "terminations of households" and motivate this choice by the fact that most widows choose to delay their children's inheritance until their own deaths. This designation also simplifies the analysis because children, by default, will inherit the estate in proportional shares in all such cases. The default sharing rules can be partially offset by the existence of a will, but an offspring's entitled share of the estate cannot be reduced to less than 50% of the default. Moreover, opting out of the default sharing rule is extremely rare—only 2% of the empirically relevant individuals in Denmark have drafted a will (Ret og Råd 2008). Consequently, the net wealth of the estates in our sample is divided equally among the offspring.

Identification of estates is facilitated by the deceased's institutional environment. Danish law requires that a doctor issue a death certificate when a citizen dies. If the person dies at home, the death certificate is filled out by the deceased's personal doctor or the emergency doctor on duty (*Lægevagten*). If the person dies in the hospital, a doctor at the hospital will issue the death certificate. Danish law further obliges the relatives to report the death to their local funeral authority within two days. The funeral authority formally notifies relevant government agencies, including the Central Office for Personal Registration (*CPR Registeret*) and the Probate Court (*Skifteretten*). The latter supervises the processes that transfer legal title of property from the deceased's estate to the beneficiaries. *Skifteretten* immediately seizes the deceased's assets with the purpose of meeting liabilities, and transfers the net worth to the beneficiaries according to the sharing rule established by the inheritance law and any existing wills. The inheritance law further requires that the transfer of the deceased's estate be finalized within 12 months of the date of death.

The net worth of the estate is subject to a 15% estate tax for immediate relatives (Group 1) if the estate's net wealth exceeds DKK 191,000 (EUR 25,638) in 1998. This threshold is inflated by a price index in subsequent years. The estate tax is supplemented with an additional 25% inheritance tax for people who are not immediate family members of the deceased (i.e., Group 2 or 3 relatives, which we omit in this study). The estate tax is levied on the estate's total net assets, irrespective of the underlying assets. Unrealized capital gains incurred by the deceased from financial or real estate investments are not directly taxed. Thus, beneficiaries have no tax incentives to either keep or liquidate specific assets.

2.1 Data sources

We construct a dataset of 17,191 individual beneficiaries who unexpectedly inherited wealth as a result of the sudden death of their legal parents (10,344 household terminations). Our dataset contains economic, financial, and personal information about the individuals and their deceased parents. The data were collected from relevant official registers. Demographic, income, and wealth data are comparable to the data from Sweden used by [Calvet, Campbell, and Sodini \(2007, 2009\)](#). The information on the official medical causes of death in our data, however, provides a novel source for the identification of wealth shocks. The dataset was constructed from four different sources made available from Statistics Denmark, as explained below.⁶

A. *Individual and family data* are from the official Danish Civil Registration System. These records include the personal identification number (*CPR*), name, gender, date of birth, names and *CPR* numbers of nuclear family members (parents, siblings, and children), and marital history (number of marriages, divorces, and widowhoods). In addition to providing control variables, such as age, gender, and marital status, these data enable us to identify all individuals' legal parents. The sample contains the entire Danish population, and provides unique identification across individuals and households over time.

B. *Income and wealth information* is from the official records of the Danish Tax Authorities (*SKAT*). This dataset contains personal income and wealth information, sorted by *CPR* number, about the Danish population. *SKAT* receives this information directly from the relevant sources: Financial institutions supply information to *SKAT* on customers' deposits, on interest paid or received, and on security investments and dividends. Employers similarly supply statements of wages paid to their employees. Through Statistics Denmark, we obtain access to personal income and wealth data from 1990 to 2006. However, investments in stocks were self-reported prior to 1997. A 1997 tax reform changed the source of the financial wealth data from self-reporting to mandatory reporting directly by financial intermediaries. As a result, we have reliable data for the entire Danish population on individuals' stock holdings from 1997 to 2006. Information on stock holdings includes direct investments and indirect investments through mutual funds. We index all income and wealth variables to year-2000 DKK throughout the analysis.

C. *Causes of deaths* are from the Danish Cause-of-Death Register at the Danish National Board of Health (*Sundhedsstyrelsen*). In this dataset, the cause of death is classified according to international guidelines specified by the World Health Organization's (WHO) International Classification of Diseases

⁶ Collectively, these data are available for researchers through Statistics Denmark, but one has to obtain permission to access individual, confidential data. Access is granted to researchers associated with academic institutions but, due to its sensitive nature, the data cannot be exported from the closed server environment provided by Statistics Denmark.

(ICD-10) system.⁷ The sources of this data are the official death certificates that are issued immediately after the death of every Danish citizen. The death certificate details the cause of death based on post-mortem examination reports, information on social and psychiatric history provided by family members and associates, and other corroborating information, such as suicide notes. In Denmark, both the death certificate and the post-mortem examination report are completed by a doctor and, therefore, convey a medically qualified opinion on the cause of death. *Sundhedsstyrelsen* compiles these data for statistical purposes, and makes them available for medical and social science research through Statistics Denmark. We obtain the cause of death for all Danish citizens who passed away from January 1, 1998, through December 31, 2003. We use this dataset to identify a sample of individuals who died suddenly and unexpectedly.

D. *Educational records* are from the Danish Ministry of Education. All completed (formal and informal) education is registered on a yearly basis for each individual and made available through Statistics Denmark. We use these data to measure an individual's education level, and to identify individuals who either have formal (university) education in economics or finance, or, alternatively, have obtained knowledge about finance through apprenticeships in the financial industry.

2.2 Data construction

To identify individuals whose parents have died, we link the data on cause of death to the family data using CPR numbers. Thus, the starting point of our analysis is deaths of parents that cause a termination of household. Terminations of households occur whenever the last living parent dies, or when both parents die within the same calendar year. In total, we identify 71,081 terminations of households between 1998 and 2003. Panel A in Table 1 shows the distribution across time. From this sample, we identify the cause of death for the purpose of selecting a sample of household terminations resulting from sudden and unexpected death. Panel B details the cause of death based on WHO's ICD-10 codes.

To identify sudden and unexpected deaths, we rely on a medical literature that defines sudden death as unexpected death that occurs instantaneously or within a few hours of an abrupt change in the person's previous clinical state. To identify the relevant ICD-10 codes, we search the medical literature and inspect WHO's detailed classification system.⁸ The medical literature distinguishes between natural and unnatural deaths, where natural deaths are due

⁷ WHO's International Classification of Diseases, ICD-10, is the latest in a series that has its origin in the 1850s. The first edition, known as the International List of Causes of Death, was adopted by the International Statistics Institute in 1893. WHO took over the responsibility of ICD at its creation in 1948, and the system is currently used for mortality and morbidity statistics by all member states. The current ICD-10 standard came into use in 1994.

⁸ See WHO's webpage at www.who.int/classifications/icd/en.

Table 1
Causes of household terminations, 1998–2004

	IDC10	Year						Total
		1998	1999	2000	2001	2002	2003	
A. Household terminations	A00-Z98	10,188	11,130	11,500	12,175	12,782	13,306	71,081
B. Deceased's cause of death								
Natural	A00-R99	9,561	10,444	10,832	11,533	12,193	12,741	67,304
Acute myocardial infarction (a)	I22-I23	81	99	79	87	17	2	365
Cardiac arrest (b)	I46	60	73	87	78	106	123	527
Congestive heart failure (c)	I50	744	822	918	951	1044	1,109	5,588
Stroke (d)	I60-I69	228	270	213	276	336	346	1,669

Average number of beneficiaries		1.69	1.66	1.69	1.76	1.62	1.78	1.70
Number of beneficiaries		169	253	254	206	227	253	1,362

Note: This table shows the cause of death for terminated households from 1998 to 2004. A household is terminated whenever the last member dies or, in rare cases, when a couple dies within the year. ICD-10 is the World Health Organization's International Classification of Diseases. Codes are natural deaths (A00-R99) and unnatural deaths (V00-Z98). Within both natural and unnatural deaths, Panel B shows the number of sudden deaths caused by acute myocardial infarction (I22-I23), cardiac arrest (I46), congestive heart failure (I50), stroke (I60-69), sudden unexpected death by unknown cause (R95-R97), traffic accidents (V00-V89), and other accidents and violence (V90-V99, X00-X59 & X86-X90). Other accidents and violence do not include suicides or violence caused by relatives of the deceased.

to diseases and declining health, and unnatural deaths are the result of accidents and violence (see, for example, Li, Precht, Mortensen, and Olsen 2003). Among natural deaths, acute myocardial infarction (ICD-10: I22-I23), cardiac arrest (I46), congestive heart failure (I50), stroke (I60-I69), and sudden deaths from unknown causes (R95-R97) are considered to be sudden deaths. Among unnatural deaths, traffic accidents (V00-V89), and deaths caused by other accidents and violence (V90-V99, X00-X59, and X86-X90), are sudden and unexpected by the relatives. The latter category excludes suicide and violence by subjects related to the deceased. Panel B in Table 1 tabulates the number of deaths for subcategories of sudden deaths, whereas Panel C in Table 1 shows the total number per year. In total, we identify 10,344 terminations of households resulting from sudden deaths between 1998 and 2003.

The final step in our sample selection is to link the deceased to their beneficiaries. On average, each terminated household had 1.66 beneficiaries (i.e., children aged 18+), which expands our sample size to 17,191 individuals who experience a wealth windfall as a result of the sudden deaths of their parents. Panel D in Table 1 shows the subsample of household terminations where both

parents die suddenly within the same year. In total, we find 801 such cases, corresponding to 1,362 beneficiaries. We use this subsample as a robustness check because, everything else equal, inheritance in this group is more surprising. Once the final step is carried out, all of the individual characteristics of the beneficiaries can be identified by linking beneficiaries' information through CPR numbers.

Table 2 presents summary statistics of our final sample. As the main focus is to identify entry and participation constraints in the stock market, we split our sample into pre-inheritance participants and non-participants. For each beneficiary, we observe stock market participation, income, wealth, age, gender, education, and marital status for the year prior to the parent's sudden death. After-tax income and wealth are indexed to constant year-2000 DKK. On average, 21.7% of the beneficiaries participated in the stock market. Among participants, 33.6% of their financial wealth was invested in stocks. As is consistent with prior literature, Table 2 shows that, in the cross-section, stock market participants have significantly higher income and wealth, are older, and are better educated than non-participants. Prior literature interprets these cross-sectional

Table 2
Descriptive statistics: Characteristics of pre-inheritance stock market participants versus non-participants

	All	Pre-inheritance stock market participation		Difference (1)–(2)
		Yes (1)	No (2)

Married (%)	52.29 (49.94)	60.62 (48.87)	49.99 (50.00)	10.63***
Children in household (%)	49.05 (49.99)	47.61 (49.95)	49.50 (50.00)	-0.02**
N	17,191	3,728	13,463	

Note: We report descriptive statistics: mean and standard deviation for all beneficiaries, beneficiaries that are pre-inheritance participants and non-participants, respectively. For each beneficiary, we observe income after tax, wealth, age, gender, years of schooling, marital status, and whether there are children in the household. For each set of descriptive statistics, we also compute the difference in the average characteristics of pre-inheritance participants and non-participants, and test whether these differences are significantly different from zero. All amounts are in thousand year-2000 DKK. Standard errors are in parentheses, and *t*-statistics are in square brackets. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

differences in individual characteristics of participants and non-participants as evidence of fixed entry and participation costs. Table 2 also shows that men and married individuals are more likely to participate in the stock market.

2.3 Empirical strategy

We formally test whether fixed costs explain non-participation in the stock market by identifying the effect of windfall wealth on participation around the time of the parent's sudden death. If fixed costs deter participation, we expect individuals to participate if the windfall is large enough to incur the fixed costs. As our main purpose is to understand the impact of fixed costs on entry and exit decisions, we split the sample into individuals that are non-participants before the event and individuals that are participants before the event. We examine the entry decision for non-participants and the ongoing participation decision for participants in separate analyses to isolate the effect of fixed entry costs on participation from reoccurring, ongoing participation costs.

Our comparison of individuals' participation choices before and after receiving windfall wealth is attractive because it effectively controls for time-invariant individual characteristics (e.g., ability and education), which are likely to affect the decision to participate in the stock market. One concern with this approach is that individuals might choose to participate because their income and wealth over time allow them to, or because the cost of participation decreases over time. We therefore compare the treatment group to a control group of individuals with the same characteristics who do not receive windfall wealth.

The control group is a matched sample of individuals from the Danish population, with the same age, gender, and education level, and from the same rank (vigintile) in terms of the income and wealth distribution as the treated individuals. Moreover, we condition the matched sample on the participation decision such that we compare the reaction for pre-inheritance non-participants (participants) to a control group of non-participants (participants). For each control group, we calculate the average stock market participation, which represents the expected change in participation for the non-treated conditional on individual characteristics. This approach provides us with a difference-in-differences estimate of the effect of windfall wealth on stock market participation.

All empirical estimates in this study are based on a difference-in-differences specification. The difference-in-differences approach effectively controls for time-invariant heterogeneity. This control is important, as inherited wealth might correlate with individual characteristics (e.g., ability) related to social heritage. We also include control variables that focus on changes in individual characteristics that are likely to affect income, wealth, and, ultimately, stock market participation. We refer to these variables as preference shifters.⁹

⁹ This strategy follows directly from Brunneimeier and Nagel (2008), and captures investment reallocations that result from major changes in household status.

These preference shifters include indicator variables if the individual marries, divorces, has children, or changes educational status during the event window. We also include year fixed effects to control for individual-invariant time effects. Finally, we note that each observation consists of only one observation before and one observation after the event, thus keeping concerns about serial correlation to a minimum (Bertrand, Duflo, and Mullainathan 2004).

3. Empirical Results

3.1 Entry and participation costs in the stock market

Table 3 provides the first insights into the effect of inherited wealth on stock market participation by comparing participation before and after the unanticipated inheritance. Panel A focuses on the entry decision for pre-inheritance non-participants, whereas Panel B reports results for the continued participation decision for pre-inheritance participants.

Panel A shows that, for the subsample of pre-inheritance non-participating individuals, 13.1% chose to enter the stock market three years after receiving windfall wealth. This increase is significantly different from zero at the 1% level. The expected participation absent any windfall is 8.8 percentage points, as shown for the matched sample of non-participating individuals with the same age, gender, income, and level of wealth. The difference in differences of

Table 3
Difference-in-differences estimation of the effect of unexpected inheritance on stock market participation

	Sample		Difference (1)-(2)
	Unexpected inheritance (1)	Matched (2)	
A. Entry			
Before	0.000	0.000	0.000 (0.000)
After	0.131	0.088	0.043*** (0.003)
Difference	0.131*** (0.003)	0.088*** (0.001)	0.043*** (0.003)
N	13,463		
B. Continued participation			
Before	1.000	1.000	0.000 (0.000)
After	0.857	0.855	0.002 (0.005)
Difference	-0.142*** (0.006)	-0.144*** (0.003)	0.002 (0.005)
N	3,728		

Note: Unexpected inheritance is our sample of individuals who suddenly inherit their parents' estates. The matched sample is a control group of individuals of the same age, gender, length of education, and rank (vintile) of both income and wealth distribution. Panel A reports the entry decision for the subsample of pre-inheritance non-participants one year before and three years after the sudden death event, and differences in these measures around the event. Panel B presents before, after, and differences for continued participation decisions for the subsample of pre-inheritance participants. Standard errors are in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

4.3 percentage points is significant at the 1% level and implies that, compared with the entry rate of the control group, windfall wealth induces an additional 4.3% of non-participating individuals to enter the stock market. Although this increase is consistent with fixed entry costs, the estimated effect of less than 5 percentage points is surprisingly low given the emphasis on fixed entry costs in prior literature.

In Panel B, we focus on the continued participation decision for the subsample of pre-inheritance participants. If individuals face ongoing participation costs in the stock market, we would expect more of those who received windfall wealth to stay in the stock market than those in the control group. After receiving windfall wealth, 85.7% of the individuals still chose to participate in the stock market, compared to 85.5% for the matched sample. The difference in differences of 0.2 percentage points is insignificant. Thus, receiving an unexpected and sudden inheritance appears to have little effect on continued participation, and the same fraction of beneficiaries and non-beneficiaries exits the stock market following a sudden inheritance event. This evidence points to entry costs as the main participation costs.

One obvious explanation for these relatively modest reactions to unanticipated inheritance is that the windfall might be too small to offset the fixed costs. Table 4, therefore, shows the difference-in-differences estimates for deciles of

Table 4
Difference-in-differences estimation of the effect of unexpected inheritance on stock market participation by deciles of inherited wealth

Inherited wealth decile	Mean inherited wealth (DKK 1,000)	Before (1)	After (2)	Difference (1)–(2)	Difference in Differences

10	2,616.8	1.000	0.946	–0.054***	0.048***

Note: This table presents the average stock market participation one year before, three years after, the difference in participation, and difference in differences in participation around the sudden inheritance by deciles of inherited wealth. Difference in differences is the difference between the sudden inheritance sample and a matched sample of individuals with the same age, gender, length of education, and rank (vigintile) of both income and wealth distribution (see Table 3). Inherited wealth is in thousand year-2000 DKK. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

inherited wealth. Table 4 sorts the inheritance sample according to the size of windfall wealth. For the bottom 20% of those individuals with a parent who suddenly dies, the net worth of the estate is equal to zero. Thus, for this group we expect a marginal response in stock market participation. For the top decile of the distribution, the mean inheritance is DKK 1.162 million (EUR 156,000). For this group we expect to see significant changes if fixed participation costs matter.

Consistent with this argument, Table 4 reveals that the effect on participation increases with inherited wealth. For low levels of windfall wealth, the response is almost identical to the matched sample, while it is 22.7 percentage points in the top decile. We observe a small negative response in the lowest deciles, which is contrary to intuition. For low deciles of windfall wealth, the average net worth of the estate is quite small, and perhaps not large enough to cover the cost of the funeral or costs related to the termination of the household (lawyers, movers, cleaners, etc.).¹⁰ Still, the most striking result in Table 4 is that, even for the top decile of inherited wealth, only 35% of non-participants respond to windfall wealth by entering the stock market. Thus, almost two-thirds of these individuals remain non-participants despite receiving significant windfall wealth averaging DKK 1.2 million. Considering the size of the average windfall within this group, this result appears inconsistent with the conclusion that fixed costs offer the main explanation for non-participation.

Panel B shows difference in differences for continued participation across deciles of windfall wealth. Continued participation increases with inherited wealth, although the effects are quite modest. The difference in differences are only significant for the two top deciles. Even among these individuals, who receive large windfalls averaging DKK 2.6 million, around 5% still choose to sell out. Thus, in keeping with the estimates in Table 3, we find little evidence to suggest that ongoing participation costs are important in explaining stock market participation outcomes.

Although the difference-in-differences estimates successfully control for time-invariant individual heterogeneity (e.g., ability and social heritage) that might affect stock market participation, individuals' household status (e.g., marital status) might change over time. In Table 5, therefore, we run cross-sectional regressions of the difference in differences on inherited wealth while controlling for preference shifters and year fixed effects.

In column 1 of Table 5, we regress the difference in differences on the amount of inherited wealth and find that the probability of entering the stock

¹⁰ According to the [Danish Ministry of Finance \(1998\)](#), the average funeral cost is DKK 8,400 if the body is cremated and DKK 9,300 if it is buried (in year-2000 DKK). Pre-arranged (and pre-paid) funerals are rather uncommon in Denmark, and represent less than 10% of all funerals. This fraction is expected to be lower in our sample of sudden deaths and, as a result, beneficiaries will generally be those to arrange the funeral. The funeral costs probably mean that beneficiaries in the low-wealth deciles experience a small negative wealth shock and are, therefore, less likely to invest in stocks than those in the matched sample.

Table 5
Inherited wealth, and stock market entry and continued participation decisions

Decision	Entry		Continued participation	
	(1)	(2)	(3)	(4)
Inherited wealth	0.1230*** (0.0054)	0.2263*** (0.0081)	0.0035 (0.0035)	0.0244*** (0.006)
Inherited wealth squared		-0.0141*** (0.0009)		-0.0008*** (0.0002)
Preference shifters	Yes	Yes	Yes	Yes
Year fixed effects	Yes	Yes	Yes	Yes
N	13,463	13,463	3,728	3,728
Adj. R-squared	0.040	0.056	0.001	0.001

Note: The dependent variable is the difference in differences in stock market participation one year before and three years after the sudden inheritance. Difference in differences is the difference between the change in the treatment group receiving windfall wealth and a matched control sample. The matched sample consists of individuals of the same age, gender, length of education, and rank (vigtile) of both income and wealth distribution. *Inherited wealth* is measured in millions year-2000 DKK. *Inherited wealth squared* is the square of inherited wealth. *Preference shifters* include controls (indicator variables) for changes in marital status, family size, and education. Standard errors are in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

market (relative to the matched sample) is 12.3 percentage points higher for each million DKK (EUR 134,000) of inherited wealth. In column 2, we include a squared term of inherited wealth, which captures the implication of a fixed-cost argument that the marginal effect of wealth on stock market participation is decreasing. Consistent with this argument, we find that the square term is negative and significant at the 1% level. The marginal effect of the first million DKK of inherited wealth implies a 21.2 percentage point higher probability of participation, compared to a marginal effect of 18.4 percentage points for the next million. Although our difference-in-differences estimates provide evidence of fixed entry costs in the stock market, the estimated effects are relatively small—even substantial windfall wealth of DKK one million (EUR 134,000) only increases participation rates by around 21.2 percentage points.¹¹

Columns 3 and 4 focus on continued participation. Column 3 shows that windfall wealth of DKK one million (EUR 134,000) only implies a 0.4 percentage point higher probability that the beneficiary will stay in the stock market. Although the marginal effect of inherited wealth increases when we include a squared term in column 4, the effects are still small. Even large windfalls can only explain a trivial fraction of the variation in the ongoing participation decisions. Thus, although the evidence is supportive of fixed ongoing participation costs, it appears to be a second-order effect.

¹¹ In comparison, the marginal effect on participation of DKK one million in wealth is 6% in the cross-section and only 1% when using the panel dimension. Thus, compared to the results from the natural experiment, cross-sectional and panel data estimates are significantly biased.

3.2 More evidence on entry and participation costs

In this section we exploit variation in characteristics of beneficiaries to understand how age, education, and financial literacy affect fixed entry and ongoing participation costs.

In column 1 of Table 6, we show how age matters for stock market participation. If one-time entry costs are important, we expect older individuals to respond less than younger beneficiaries to windfalls because older individuals have a shorter time horizon in which to harvest the benefits of the sunk cost. Alternatively, we expect age to have a negligible effect if the fixed costs represent only ongoing participation costs. To investigate this effect, we interact age with inherited wealth. Column 1 shows no direct effect of age but a significant effect on participation when age is interacted with the size of windfall wealth. Although, at first glance, the interaction term seems small, the marginal

Table 6
Inherited wealth and the size of fixed entry costs

N	13,463	13,463	13,463	13,463
Adj. R-squared	0.067	0.063	0.062	0.063

Note: The dependent variable is the difference in differences in stock market participation one year before and three years after the sudden inheritance. Difference in differences is the difference between the change in the treatment group receiving windfall wealth and a matched control sample. The matched sample consists of individuals of the same age, gender, length of education, and rank (vigintile) of both income and wealth distribution. *Inherited wealth* is measured in millions year-2000 DKK. *Inherited wealth squared* is the square of inherited wealth. *Age* is measured in years. *Financially literate* is an indicator taking the value one if the individual has a university degree in economics, finance, or a related field, or has obtained, through an apprenticeship in the financial industry, knowledge about financial markets. Preference shifters include controls (indicator variables) for changes in marital status, family size, and education. Standard errors are in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

effect of inheriting DKK one million is 41.8 percentage points for a 20-year-old individual, compared to only 9.8 percentage points for a 60-year-old. We interpret this as evidence of one-time costs related to entering the stock market. This finding also bolsters our main argument that sudden bequests do provide an exogenous shock to wealth because windfalls are more unanticipated for young individuals.

In column 2 of Table 6, we examine how education matters for stock market participation. If education lowers the participation costs, as is argued in the literature, we expect to find a direct effect of education on participation but a smaller effect per dollar of inheritance when controlling for the education level. Simply put, individuals with higher levels of education should react more positively to even small levels of windfall wealth than individuals with lower levels of education. Moreover, this difference in participation outcomes related to educational levels should decline as inherited wealth increases.

We find that the length of education has a direct, statistically significant effect on participation and that inheritance has a smaller per-dollar effect for highly educated individuals—although these differences are modest. Each additional year of education raises the participation rate by 0.52 percentage points, whereas DKK one million of inherited wealth decreases this effect by 0.59 percentage points per year of schooling. To evaluate the joint effect, one has to add the direct effect of inherited wealth to the interacting effect of education. Consequently, a high-school dropout with 10 years of schooling is 7.6 percentage points more likely to enter the stock market when he inherits DKK 100,000. When inherited wealth increases to DKK one million, the marginal effect on participation increases to 27.4 percentage points. In comparison, an individual with a university degree (17 years of schooling) will be 10.8 and 26.9 percentage points more likely to participate when inheriting DKK 100,000 and DKK one million, respectively. Thus, for small windfalls, the highly educated respond more positively to inherited wealth. This difference diminishes as inherited wealth increases. This finding bolsters the interpretation given in much of the prior literature that individuals with longer periods of education have lower fixed objective costs.

One potential explanation of the low explanatory power of fixed costs in the natural experiment is that some individuals might be unaware of the existence of stocks as an asset class. For instance, Guiso and Jappelli (2005) report that over 35% of Italian households in the mid- and late 1990s were apparently unaware of stocks. On the other hand, Campbell (2006) argues that although this might explain non-participation in some countries, the proportion is likely to be much smaller in countries with more developed financial markets. To ascertain that our results are not driven by unawareness, we examine whether the reactions to windfall wealth are different for individuals who are financially literate.

In columns 3 and 4 of Table 6, we define an indicator for financially literate individuals who either hold a university degree in economics, finance, or

related disciplines, or have obtained an informal education during an apprenticeship in the financial industry. Consistent with the general effect of education, we find that financially literate individuals are 9.7 percentage points more likely to enter the stock market. This effect appears to decline with inherited wealth, although the low number of observations makes it difficult to estimate the coefficient with precision. Financially literate individuals who inherit DKK one million have a 7.0 percentage point higher probability of entering the stock market. This effect remains significant even when controlling for the direct effect of education (column 4). In summary, unawareness does not play a major role in explaining non-participation in our setting.

3.3 The effect of investment inertia and procrastination

Two plausible explanations for the modest response to windfall wealth are investment inertia and procrastination. We examine these possible explanations separately. The effect of inertia is addressed by extending the horizon of the evaluation period. Procrastination is examined by analyzing whether the composition of the inherited estate's portfolio matters for beneficiaries' portfolio choice.

If individuals are slow to change their investment decisions, inertia will negatively bias the estimated effect of inherited wealth on stock market entry. Prior literature has documented the presence of inertia in asset allocation. Participants in retirement savings plans, for instance, rarely alter the allocations of their contributions or rebalance their portfolios (Madrian and Shea 2001; Agnew, Balduzzi, and Sundén 2003; Ameriks and Zeldes 2004; Choi, Laibson, Madrian, and Metrick 2002; 2004). Consistent with inertia, capital gains and losses have also been found to generate little portfolio rebalancing in US survey data studied by Brunnermeier and Nagel (2008).

In Table 7, therefore, we look at the effect outside the current event window, which spans from year -1 to $+3$. In particular, we examine when inherited wealth has predictive power in explaining the stock market entry decision (columns 1 to 3) and the continued participation decision (columns 4 to 6) in alternative windows, covering the initial period from -1 year to $+1$ year, and subsequent periods from year $+1$ to year $+3$ and from year $+3$ to year $+5$. For the entry (ongoing participation) decision, our sample includes only non-participants (participants) at the beginning of each event window. Thus, the marginal effects identify the effect of delaying the investment decision on account of inertia.

We find some evidence of investment inertia, as inherited wealth is positively related to participation decisions in subsequent periods. Individuals who inherit DKK one million are 8.9 percentage points more likely to decide to enter the stock market from year $+1$ to year $+3$. However, in the subsequent event window, from year $+3$ to year $+5$, we only find insignificant effects of inherited wealth on participation. Thus, although some individuals do delay

Table 7

Note: The dependent variable is the difference in differences in stock market participation for alternative event windows. Difference in differences is the difference between the change in the treatment group receiving windfall wealth and a matched control sample. Columns 1 through 3 are entry into the stock market. Columns 4 through 6 are decisions to exit the stock market. The matched sample consists of individuals of the same age, gender, length of education, and rank (vigintile) of both income and wealth distribution. *Inherited wealth* is measured in millions year-2000 DKK. *Inherited wealth squared* is the square of inherited wealth. Preference shifters include controls (indicator variables) for changes in marital status, family size, and education. Standard errors are in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

the investment decision on account of inertia, inertia cannot explain the surprisingly low effect of fixed entry costs on stock market participation in our main window from -1 to +3.

Columns 5 and 6 show that inherited wealth has a limited and only marginally significant effect on ongoing participation decisions in subsequent periods. This is consistent with our general finding that ongoing participation costs seem to be a second-order effect in explaining why individuals leave the stock market.

The second aspect of investment inertia is related to procrastination. Prior literature demonstrates that procrastination plays an important role in individuals' savings and investment decisions. For instance, *Madrian and Shea (2001)* show that 401(k) enrollment rates are significantly higher under automatic enrollment of employees. If the participation decision in our setting is affected by procrastination, inheriting an estate holding stocks should increase the probability of participation simply because it changes the active decision from deciding to enter the stock market to choosing to exit the market. The institutional setting is helpful in identifying the effect of procrastination because potential capital gains are not subject to taxation in the event of inheritance. Thus, inheritance tax is solely determined by net wealth and is unaffected by the composition of that wealth.

In column 1 of Table 8, therefore, we include an indicator variable that takes the value 1 if the estate held stocks. Of the 13,463 non-participants in the sample, 3,208 beneficiaries (23.8%) inherited from an estate that held stocks. The effect of inheriting stock on participation rates is both economically and statistically significant. Inheritance of stocks increases the participation rate

Table 8

N	13,463	13,463	13,463
Adj. R-squared	0.084	0.064	0.085

Note: The dependent variable is the difference in differences in stock market participation one year before and three years after the sudden inheritance. Difference in differences is the difference between the change in the treatment group receiving windfall wealth and a matched control sample. The matched sample consists of individuals of the same age, gender, length of education, and rank (vintile) of both income and wealth distribution. *Inherited wealth*, *inherited wealth excluding stocks*, and *value of inherited stocks* are measured in millions year-2000 DKK. *Inherited estate held stocks (0/1)* is an indicator variable for whether the estate held stocks. Preference shifters include controls (indicator variables) for changes in marital status, family size, and education. Standard errors are in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

by 12.7 percentage points. However, this effect might capture the fact that wealthier estates are more likely to hold stocks. In column 2, therefore, we split inherited wealth into two covariates: inherited wealth excluding stocks and value of inherited stocks. Inherited wealth excluding stocks has almost the same effect on participation as the effect tabulated in Table 5: DKK one million in inheritance from sources other than stocks implies an 18.0 percentage point higher probability of participation. Now, compare this to the estimated coefficient on the value of inherited stocks. Inheriting DKK one million worth of stocks increases the probability of stock market participation by 43.7 percentage points. Thus, the effect of inheriting stocks on participation is significantly greater than that of inheriting cash in both economic and statistical terms.

In column 3, we expand the specification by including the indicator variable for inheriting stocks. Again, the indicator variable for inheritance of stocks is positive and highly significant. If the estate held stocks, the probability of participation increases by 12.2 percentage points. The difference between the first inherited million DKK worth of stocks compared to inheriting cash is only 9.3 percentage points. Still, despite the marginal effect of procrastination, fixed costs cannot explain why the majority of individuals shy away from stocks.

The evidence in Table 8 is also helpful in addressing whether non-participation is caused by borrowing constraints, as suggested by Constantinides, Donaldson, and Mehra (2002) and Davis, Kubler, and Willen (2006). In the presence of credit constraints, a bequest increases wealth and reduces this constraint. As such, our identification strategy does not directly identify whether non-participation is initially caused by borrowing constraints. However, given that individuals who inherit large positions of stocks sell out, borrowing constraints are unlikely to explain the results.

3.4 Interpretation

We use exogenous variation in an individual’s wealth to identify the relative importance of fixed entry and participation costs in understanding why people shy away from the stock market. Although we generally find evidence consistent with the existence of such costs, our results demonstrate that these costs have relatively modest power in explaining limited participation. Three years after receiving windfall wealth, only 13.1% of all beneficiaries have invested in stocks. Of those individuals receiving inheritances of more than DKK one million, around one-third enter the stock market, while two-thirds remain non-participants.

Our ability to infer that non-participation for the majority of households cannot be explained by fixed costs hinges on the assumption that individuals actually keep some of the windfall as financial wealth. If the entire inheritance is instantly consumed, we might learn little about investment behavior and more about individual preferences to consume inheritance. Table 9 reports the holdings of financial wealth in cash and bonds both before and after receiving inheritance for individuals who remain non-participants. In addition, it includes the distribution of the change in financial wealth. Panel A reports

Table 9
Interpretation: Are non-participants holding financial wealth at all?

	Distribution of change in financial wealth relative to pre-inheritance					Average financial wealth (DKK 1,000)		
	<25%	25–50%	50–75%	75–100%	>100%	Pre-inheritance (Year -1)	Post-inheritance (Year +3)	Difference
A. All								
Individual	0.402	0.053	0.039	0.036	0.471	36.5	68.3	31.8
Household	0.388	0.063	0.051	0.041	0.457	88.8	296.4	207.6
B. Windfall wealth > DKK 1 million								
Individual	0.275	0.022	0.022	0.030	0.652	67.1	125.8	58.7
Household	0.217	0.051	0.032	0.046	0.655	147.1	512.0	364.9

Note: All panels report financial wealth for beneficiaries that remain non-participants after receiving windfall wealth. Financial wealth is the sum of bonds and cash, and is reported pre-inheritance (year -1) and post-inheritance (year +3). Panel A shows individual and household holdings for all beneficiaries, while Panel B shows the holdings for beneficiaries receiving windfall wealth of DKK one million or more. If bank accounts are shared within the household, the reported holding of cash on the individual level is equal to half of the total holdings on the household level. All numbers are in year-2000 DKK.

financial wealth for all individuals, and Panel B reports financial wealth for individuals receiving more than DKK one million in inheritance. The average holding of financial assets almost doubles for individuals who receive windfall wealth. The average beneficiary increases his/her holdings of financial assets by DKK 31,800 (EUR 4,300). More importantly, for individuals who receive large windfalls of more than DKK one million, financial assets increase by DKK 207,600 (EUR 27,900). Most of this increase comes from bank accounts that often carry the name of both the beneficiary and his/her spouse. Individual holdings will mechanically underestimate the change in financial wealth due to inheritance because deposits in bank accounts with two account holders count for only half on the individual level. In Panel B, therefore, we aggregate to the household level. The financial wealth increases on average by DKK 58,700 (EUR 7,900) to DKK 125,800 (EUR 16,900). For households receiving large windfalls of more than DKK one million, financial wealth increases by DKK 364,900 (EUR 49,000) to DKK 512,000 (EUR 68,700). Finally, Table 9 shows the distribution of the change in financial wealth. Around two-thirds of the individuals receiving windfall wealth of more than DKK one million increase their financial wealth by more than 100%. Thus, individuals who receive large windfalls and remain non-participants have substantial financial wealth.

The fixed-cost theory calculates a dollar value for the likely benefit of participation given financial wealth, the fraction of financial wealth in stocks conditional on entry, and the (certainty equivalent) expected excess return on the stock market. If those individuals who remain non-participants invest the same fraction of their financial wealth in stocks as participants (33.6%), then the potential yearly benefit from participation for individuals receiving large windfalls is equal to DKK 8,600 (EUR 1,150) per year, assuming a 5% certainty equivalent excess return on stocks (after tax).¹² To be able to explain non-participation by means of ongoing participation costs, these costs have to exceed the yearly benefit from participation. To be able to explain non-participation by fixed entry costs, the entry cost has to exceed the present value of the yearly benefits of participation (which is equal to the annuity value of the estimated yearly participation benefit). Our analysis shows little evidence of ongoing participation costs, whereas fixed entry costs have some relevance in explaining non-participation. Given the large present value of the potential benefit from participation, however, fixed entry costs are unlikely to explain why many households that receive large windfalls choose not to participate.¹³ Collectively, these findings show that although fixed entry costs can account

¹² The benefit of participation is calculated as financial wealth * portfolio share in stocks * certainty equivalent excess return on stocks = 512,000 * 0.336 * 0.05 = DKK 8,600. In comparison, Vissing-Jørgensen (2002) assumes a 4% certainty equivalent for the US. Capital gains are not subject to taxation during the sample period for investors with small stock investments in Denmark, whereas US investors pay a 20% tax.

¹³ To be conservative, we ignore the impact of paying off a mortgage. As mortgages in Denmark are backed by bonds, paying off a mortgage is equivalent to increasing financial wealth invested in bonds. As a result, the estimated benefit from participation is conservative in the above calculation.

for around one-third of non-participants, the majority of individuals seem to be constrained by other factors.

4. Alternative Specifications and Robustness Checks

4.1 Focusing on accidents

One concern with the prior analysis is that although we identify deaths that appear to be sudden and unexpected to a family outsider, they might be somewhat expected by the deceased and their beneficiaries, as death is inevitable. To address this concern, columns 1 and 6 in Table 10 show results from the subsample of deaths caused by accidents. The results are very similar to those reported in Table 5. For the entry decision, the marginal effect of DKK one million of windfall wealth is a 23.0 percentage point higher probability of holding stocks after three years. The marginal effect of DKK one million of inherited wealth on continued participation is 5.2 percentage points. Thus, by focusing on accidents that, by definition, are unpredictable, we confirm the results from our analysis based on a medical definition of sudden death. This finding also bolsters our primary argument—that sudden bequests provide an exogenous shock to wealth.

4.2 Focusing on cases in which both parents died within a year

Our results might also be affected by our reliance on household terminations, which tend to be dominated by deceased widows. Given that the beneficiaries in these cases have already lost one parent, inheritance might be expected, in particular for older individuals, even if the cause of death is medically defined as sudden. To address this possibility, we identify the subsample of household terminations in which both parents died suddenly within a given year. In such cases, inheritance is more likely to be unanticipated. Columns 2 and 7 of Table 10 show the results for pre-inheritance non-participants and participants, respectively. For non-participants, our results are consistent with the prior analysis. DKK one million of inheritance has a 22.0 percentage point effect on participation, which is lower than the effect estimated in column 2 of Table 5. For pre-inheritance participants, inherited wealth also has a positive effect.

4.3 Focusing on cases without sibling rivalry

Our results on investment inertia might also be explained by potential sibling rivalry and disagreements over the division of the estate. Potential conflicts among siblings may cause a delay in the liquidation of estates with many beneficiaries, which can subsequently delay the actual transfer of inherited wealth. In columns 3 and 8 of Table 10, therefore, we focus solely on estates with a single beneficiary (i.e., a lone child), within which such conflicts are absent. Again, our results are consistent with our main analysis.

Table 10
Alternative specifications

Preference shifters	Yes	Yes	Yes	No	Yes	Yes	Yes	Yes	No	No
Year fixed effects	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes
N	2,584	1,058	4,294	10,386	11,906	602	304	1,620	3,728	3,057
Adj. R-squared	0.065	0.081	0.063	0.049	0.066	0.007	0.009	0.013	0.001	0.001

Note: The dependent variable is the difference in differences in stock market participation one year before and three years after the sudden inheritance. Difference in differences is the difference between the change in the treatment group receiving windfall wealth and a matched control sample. We use four different subsamples: *Accidents* include household terminations caused by traffic accidents, *Both parents* includes household terminations in which both parents died within the year, *No siblings* includes household terminations with a single beneficiary, *Household level* includes the household of the beneficiaries if the household's characteristics are stable during the evaluation period (see Section 3.4). The matched sample consists of individuals of the same age, gender, length of education, and rank (vignette) of both income and wealth distribution in columns 4 and 9, the matched sample consists of households with the same average age, highest length of education, number of household members, and rank (vignette) of both income and wealth distribution. In columns 5 and 10, the matched sample consists of individuals with parents of the same age in addition to the general match characteristics. *Inherited wealth* is measured in millions year-2000 DKK. Preference shifters include controls (indicator variables) for changes in marital status, family size, and education. Standard errors are in parentheses. ***, **, * and * denote significance at the 1%, 5%, and 10% levels, respectively.

4.4 Aggregation to household decisions

All of our results focus on beneficiaries' individual investment decisions. One valid concern is how individual behavior differs from household behavior and, in turn, how assets are reallocated within the family. In unreported regressions, we have aggregated the analysis to the household level without detecting any meaningful differences in the results. In the aggregation, we consider only households with stable characteristics during the event window.¹⁴ Thus, if the household experiences death or divorce, we exclude the observation from the sample.

In columns 4 and 9 of Table 10, we report the general effect on the household level of inherited wealth on the entry and exit decisions, respectively. The marginal effect of windfall wealth on participation is 21.6 percentage points, which is coherent with our prior findings. Thus, our main result, which suggests that fixed participation costs explain little of the variation in participation decisions, is not an artifact of carrying out the analysis on the individual level.

4.5 Matching on parental age

Another concern relates to whether inheritance is anticipated. Although we restrict the sample to sudden deaths, individuals might know their parent's exact wealth and might be able to borrow against expected inheritance. To control for this possibility, we include a match on the basis of parental age along with existing match characteristics. By matching on parental age, we control for differences in behavior related to anticipated bequests. Parental age is the minimum of the age of living parents. When we match on parental age, 13 percentage points of treated non-participants—in contrast to 8.7 percentage points of those in the control group—enter the stock market after three years. This gives a difference in differences of 4.4 percentage points, which is significant at the 1% level. In comparison, we find difference in differences of 4.3 percentage points in Table 3. In columns 5 and 10 of Table 10, we further regress inherited wealth on the difference in differences while controlling for preference shifters. We note that the marginal effects are similar to the main specification, which suggests that anticipated bequests cannot explain our results.

5. Conclusions

The results from the natural experiment reveal that some individuals face entry and ongoing participation costs in the stock market. Receiving a windfall of DKK one million raises the probability of entering the stock market by approximately 21 percentage points, still leaving out many as non-participants. Although the magnitude of this result is affected by investment inertia and procrastination, we still find that the majority of individuals do not respond to

¹⁴ As a result of the focus on stable households, we do not include preference shifters in the analysis.

windfall wealth, even over long horizons. This holds even for highly educated individuals, as well as for economists and people employed in the financial industry with access to information and knowledge about the stock market. Moreover, non-participants keep substantial wealth in cash and bonds, thereby foregoing the benefits of stock market participation. Thus, although fixed entry and ongoing participation costs discourage some individuals from investing in the stock market, these factors are unlikely to explain why the majority of non-participants shy away from stocks.
